# THE MORPIIOLOGY OF GEOMAGNETIC STORMS: AN EXTENSION OF THE ANALYSIS OF $D_{\mathrm{s}}$, THE DISTURBANCE LOCAL-TIME INEQUALITY 

Sydney Chapman

## 1. INTRODUCTION

This paper describes an extension of the series of analyses of the morphology of geomagnetic storms which I began in 1917. The first results were published ( ${ }^{-a}$ ) in 1918, and were supplemented ( ${ }^{2 b}$ ) in 1927 by further results, particularly for weak magnetic disturbance and for the polar regions.

The present extended analysis was nearly completed in its present form in 1918, and its publication has been too long delayed; had the results appeared carlier a misconception (§ 6) would have been prevented, for which some words in my 1918 paper may he counted responsihle.

The present extension of the method of analysis should have useful application also in the investigation of ionospheric storms.

## 2. MATERIAL

The data for the present paper form a part of that used in my 1918 paper ( $\left.{ }^{(2 n}\right)$, and refer to the 40 moderate magnctic storms (1902-11) there discussed. Table 1 qives particulars (not previously published) for these storms, which were selected from those with sudden commencements, contained either in a list (3) compiled by E. W. Maunder (1904) from the Greenwich records up to 1903, or (for later years) from the pmblications of the U. S. Coast and Geodetic Survey for the ohservatories of Honolulu, Cheltenham (Maryland) and Sitka (Alaska). They were chosen as being all of moderate intensity. Table 1 and Figure 1 show that the storms were fairly uniformly distributed over the Greenwich day (Fig. la) (except for some excess near Greenwich midnight), and also throughout the calendar year (Fig. 1b); Fig. lc shows the inflnence of the solar cycle on their distribution from year to year, and indicates the ammal mean snnspot number for each year. Many of the storms were members of 27-day recurrences, as shown in the cohmms of $N_{d}$ in Table 1.

## Table 1

Data for 40 moderate magnetic storms, 1902-11; serial number $s ; h$ is the lour (G.M.T.) of commencement; $C$ is the international daily magnetic character figure, multiplied by 10 , for the day of commencement and the two following days; an asterisk * in the first column signifies that the day preceding the storm outbreak was specially quiet ( $C$ zero or 0.1 ); $N s$ is the number in the 27 -day sequence containing the storn (taking $N=1000$ for the sequence beginning on 1906 Jan $11)$; $N d$ is the number of the day of commencement in this sequence, or, when marked with ${ }^{*}$, the number of the following day.

| Serial number 8 | Date of beginning | Initial hour h | Character figures C | Fotation number Ns | Day number Nd |

The data here used for these storms refer to eight observatories (here numbered 1 to 8 ) in geomagnetic latitudes not exceeding $50^{\circ}$ (See Table 2); their spacing in longitude is illustrated in Fig. ld. In my 1918 paper I considered also four ohservatories in higher latitudes, Greenwich (9), Potsdam (10), Pavlovsk (11) and Sitka (12).

## Table 2

Geographic (gg) coordinates and geomagnetic (gm) latitude

|  | $\begin{aligned} & \text { Latitude } \\ & \quad g \mathrm{~g} \end{aligned}$ | $\underset{\mathrm{gm}}{\text { Latitude }}$ | Longitude (gg) |  |
| :---: | :---: | :---: | :---: | :---: |
|  |  |  | Angle | Time |
| 1. Batavia | $6^{\circ} \mathrm{S}$ |  | $107^{\circ} \mathrm{E}$ | 7h.l E |
| 2. Porto Rico | 18 N | 30 N | 65 W | 4.4 W |
| 3. Honolulu | 21 N | 21 N | 158 W | 10.6 W |
| 4. Zikawei | 31 N | 20 N | 121 E | 8.1 E |
| 5. San Fernando | 36 N | 41 N | 6 W | 0.4 W |
| 6. Baldwin | 39 N | 49 N | 95 W | 6.3 W |
| 7. Cheltenham (Md.) | 39 N | 50 N | 77 W | 5.1 W |
| 8. Pola | 45 N | 45 N | 14 E | 0.9 E |

My 1918 paper dealt with all three magnetic elements; the present results mainly refer to $H$ the horizontal intensity, and $E$ the easterly deviation (reckoned in gamma) from the mean compass direction; in addition some results are given for the vertical component ( $V$, always reckoned positive, or $Z$ if reckoned positive when downwards and negative when upwards).

The data used for each observatory and element were entered on "storm-time" Tables A, each containing 40 rows (one for each storm, $s=1$ to $s=40$ ) and 49 columns, $n=0$ to $n=48$ (in some cases there were hlank or incomplete rows where the storm data were lacking or incomplete). The column 0 referred to an epoch shortly hefore the storm logan, the later columns referred to epochs at successive later hourly intervals, after the storm had commenced; thus 2 days' data were used for each storm.

The entries in the Tables A were derived from the published tables of hourly values of the elements, and consisted of these values less the mean value of the element for the month in which the storm began; that is, they were departures from the monthly mean. The published hourly values were either instantaneous values, or (e.g. for Potsdam from 1905) means over an hour; they referred to local
mean time or to standard zone time. For each observatory the list of Greenwich times of storm commencement (Table 1) was converted into a list of times of commencement given in the time-reckoning used at the observatory. Where instantaneous hourly values were given, the mean epoch for all the entries in cohmn 0 of Table $A$ would he

Fig. 1 - The distribution of the commencement times of 40 moderate magnetic storms, over (a) the Greenwich day, (b) the year, and (c) the sunspot cycle; and (d) the longitude distribution of the 8 observatories considered in this paper.
approximately half an hour before the mean time of storm commencement; where the published data were hourly means, the corresponding interval was approximately one hour, because the mean epoch to which the published value referred had to precede the storm commencement by at least half an hour. Over the period 1902-11 most of the observatories considered in this paper gave instantaneous values.

## 3. THE METHOD OF ANALYSIS

a) The storm-time variation $D_{\text {st. }}$ - The method of analysis, already previously applied by N. A. F. Moos ( ${ }^{1}$ ) to the Bombay data, was very simple. On each Table A, the mean was formed of all the
entries in each column $n$; incomplete rows were omitted (except where they could he completed hy internolation across short gaps) in taking the means of the columns. The sequence of these means gave what I called the mean storm-time variation for the element and observatory; later I denoted it hy $D_{\text {st }}$. It is the mean variation with respect to storm-time, $t_{\mathrm{si}}$, reckoned from the time of storm commencement. The means $n=0$ to $n=48$ referred to $t_{\mathrm{st}}=-1 / 2,1 / 2, \ldots, 47 / 2$, if the published data were instantaneous hourly values.

My 1918 paper gave graphs ( ${ }^{*}$ ) of $D_{\text {st }}$ for each element for three groups of ohservatories, namely (graph 1) Nos. 1-3 (mean geomagnetic latitude $23^{\circ}$ ), (graph 2) Nos. $4-7$ ( $40^{\circ \prime}$ ) and (graph 3) Nos. 8-11 ( $32^{\prime \prime}$ ); $D_{\mathrm{st}}(\boldsymbol{E})$, for east declination, was very small; the main $D_{\text {st }}$ variation was for $H$, which increased in the first hour (hy 13 gamma, the same for all three graphs), and then decreased (in graph 1) by about 50 gamma from the maximum (and by about 40 gamma in the third graph); the minimum was reached at about $t_{\text {st }}=15^{11}$. Thereafter there was a slow recovery towards normal; the recovery was far from complete at the end of the two days considered. In $V$ the $D_{\text {st }}$ variation was similar but reversed (an initial decrease was followed by an increase); its range was much smaller, about 8 gamma in graph 1.

For the 8 observatories (numerical ( ${ }^{* *}$ ) mean geomagnetic latitude $34^{\prime \prime}$ considered in this paper the mean $D_{\text {st }}(H)$ is given in Fig. 2: the values for the hours 9 and later are smoothed by overlapping means of five.
b) The local-time variation. - The next step was to form from the Tables $A$ new "local-time" Tables $B$, two ( $B_{1}, B_{2}$ ) for each element and observatory, each with forty rows (one for each storm, as before, and with columns headed $m=1$ to $m=24$, referring to hours of local-time at the observatory. In forming the Tables B the first (pre-storm) values in the Tables $A$ were ignored. In the case of the Tables B for the elements $E$ and $V$, the entries in row $s$ were the same, except as regards order, as those on row $s$ of Table $A$; if $h_{0}$ is the local hour of the first (pre-storm) entry, $n=0$, for storm $s$ at the observatory considered, the local hour of the entry on Table A in column $n$ of the row $s$ is $h_{0}+n$, less 24 if $h_{n}+n>24$, or less 48 if $h_{0}+n>48$; the 24 entries, $n=1$ to $n=24$, of Table $A$, row $s$,

[^0]were re-written in row $s$ of Table $B_{1}$ in their appropriate local-time columns $h_{0}+n$ (or $h^{0}+n-24$ ); and the last $24, n=25$ to $n=48$, were similarly re-ordered on row $s$ of Table $B_{2}$.

In the case of the Tables $\mathrm{B}_{1}, \mathrm{~B}_{2}$ for $H$, before the reordering and entry of each hourly value according to its local time, the mean $D_{\text {st }}$ value at the foot of column $n$ of Table $A$ was subtracted from all the entries in that column, thus eliminating $D_{\text {st }}(H)$ from the

Fig. 2 - Graph of $D_{s t}(H)$, the average storm-time variation of $H$ during the first two days of 40 moderate magnetic storms; mean for 8 observatories in (numerical) mean geomagnetic latitude $34 \%$. Also the corresponding graph of $2 c_{1}$, the range of the diurnal component of $D_{\mathrm{s}}(I)$.

Tables B ; in the case of $E$ and $V$, this was not considered necessary, because $D_{\text {st }}$ in these elements is small.

The mean of the entries in each column $m$ on the Tables $B$ was calculated; the sequence of means indicated a well-marked variation according to the local time, different for each element $H, E, V$; for each element the variation showed a regular gradation from one observatory to another, with respect to change of magnetic latitude, but seemed to depend little on the longitude.

The daily variations thus found clearly differed from those characteristic of ordinary or quiet days (now denoted by $S_{4}$ ), which however, seemed still to he present, though overlaid with an additional variation.. In order to isolate the latter, $S_{\mathfrak{q}}$ was removed from the variations given by the Tables $B$. This was done by forming new Tables C, one for each element and observatory, each containing 40
rows ( $s=1$ to $s=40$ ) and 24 columns ( $m=1$ to $m=24$ ). In each row $s$ was written the series of monthly mean hourly departures from the monthly mean, for the month in which storm $s$ hegan. In the few cases where a month had two storms, the series was repeated on sheet $C$. The mean for each column gave the mean solar daily variation to he subtracted from the corresponding sequence of hourly means in the Tables $B_{1}$ and $B_{2}$ for the same element and ohservatory (it would have been better to hase Tahles $C$ on the quiet day monthly mean hourly departures, hut the change would not alter the present work very much).

The daily variation found from Tables $B_{1}$ or $B_{2}$ and $C$ in this way was called the disturbance daily variation, and later denoted by $S_{D}$. In my 1918 paper graphs (*) of $S_{\mathrm{D}}$ in $I, E$ and $V$ (or $Z$ ) were given for the ohservatories Nos. 1-3 (mean), 4-7 (mean), 8-10 (mean) and for 11, 12 separately. The curves were all substantially diurnal in character, that is, they had one main maximum and one main minimum daily, with the 24 -hour harmonic component dominant; they were quite different from $S_{4}$. The variations derived from Tahles $B_{1}$ and $B_{2}$ may he denoted by $S_{D_{1} 1}$ and $S_{\mathbf{D}^{2}}$; the $S_{0^{2}}$ variations wera similar to $S_{01}$ in type, hut were of smaller range.

In $H, S_{0}$ is approximately anti-symmetrical with respect to local noen: its amplitude decreases with increasing latitude up to about $53^{\circ}$ magnetic latitude, where $S_{0}(I)$ changes sign, the change being made rapidly over a narrow belt of latitude. At all the 8 ohservatories considered in this paper its sign was the same, so that it is suitable to take the average $S_{1}(I)$ for all 8 as indicating the type of this variation.

In $E$ and $Z, S_{\mathrm{D}}$ is reversed on crossing the equator, hut otherwise retains the same phase (not the same for $E$ as for $Z$ ) at least up to magnetic latitude $60^{\circ}$. Ilence, if the $S_{\mathrm{D}}$ variations for Batavia $E$ and $Z$ are reversed, so as to hring them into phase with those for the northern stations, the mean $S_{\mathrm{D}}(E)$ and $S_{\mathrm{D}}(Z)$ can usefully he taken, for the 8 ohservatories here considered, to illustrate the type of $S_{\mathrm{n}}$ over their range of latitude. This was the procedure adopted.

## 4. THE CIIANGING AMPLITUDE OF $S_{0}$

The decrease in amplitude of $S_{D} 2$ as compared with $S_{D^{1}}$ is analogous to the decline in $D_{\text {st }}$ in the second as compared with the first

[^1]s:orn day. But whereas the method of analysis enahles the change in $D_{\text {st }}$ to he followed continuonsly - or at least from hour to hour -the change in $S_{\mathrm{D}}$ is given only from one day to the next, that is, in the mean, from storm-time $t_{\mathrm{st}}=12^{\mathrm{h}}$ to $t_{\mathrm{st}}=36^{\mathrm{h}}$.

Certainly the part of the storm field other than $D_{\text {st }}$, represented in my 1918 paper only in the form $S_{\mathrm{D}^{1} 1}$ and $S_{\mathrm{D}^{2}}$, must, like $D_{\text {st }}$, vary continuously; by definition it is not present before the storm begins, and it must he expected to die away like the other manifestations of the storm. Thus it cannot he a true daily variation, $S_{4}$, particularly in the case of the most intense storms, whose whole active duration may he less than a day.

Nevertheless, in weak disturbance especially, as investigated ( ${ }^{(-1 / 4}$ ) in my 1927 paper, this part of magnetic disturbance manifests itself as an addition to $S_{\mathrm{u}}$, waxing and waning in intensity in rough parallelism with the degree of magnetic activity; in this form the name disturbance daily variation and the symbol $S_{D}$ are appropriate. This term and symbol will he used in reference to the difference between the solar daily variation ( $S$ ) as derived from disturbed days $\left(S_{1}\right)$ or all days $\left(S_{a}\right)$, and $S_{q}$.

## 5. THE DISTURBANCE LOCAL-TIME INEQUALITY $D_{s}$

When, however, the variation considered is obtained in the way described above, for a day (first or second) of a storm (or group of storms) having a definite beginning and a limited duration, a dificerent name and symbol seem more appropriate, and I adopt the name disturbance local-time inequality, and the symbol $D_{s}$; bere $D$, as in $D_{\text {st }}$, denotes disturbance, and $S$ refers to position relative to the meridian containing the sun, as measured by the local time. The main reason for the distinction between $S_{\mathrm{D}}$ and $D_{\mathrm{S}}$ is that $\mathrm{S}_{\mathrm{D}}$ is (by definition) the difference between two variations both definitely daily, involving 24 hours of time; whereas $D_{\mathrm{s}}$, as will appear, can he determined from smaller intervals of time, and even from individual hours or instants of stornt time. When, as described above, 24 hours of storm-time are used to determine $D_{s}$, the entries on each row of the Tables $B$ are not consecutive, except for storms for which the pre-storm local hour $h_{\mathrm{o}}$ is zero; in other cases the first $24-h_{0}$ values come at the end of the row $s$ on Table $B_{1}$, and the next $h_{\text {, }}$ values come at the beginning of the row.

Like $D_{\mathrm{st}}, D_{\mathrm{s}}$ is regarded as a function of $t_{\mathrm{st}}$, and in addition $D_{\mathrm{s}}$,
at any instant $t_{\mathrm{st}}$, depends on the local time at that instant at each station; as the local time is here to he considered as a geometrical parameter, giving the longitude of each station relative to the sun, it will he denoted hy $\mathrm{h}_{\mathrm{s}}$. Whereas $D_{\text {st }}$ represents the part of the storm field obtained ly averaging the field, at each instant $t_{\text {st }}$, all round each circle of latitude, $D_{\text {s }}$ gives the average difference hetween the instantaneous storm field and this longitudinally averaged field (symmetrical about the earth's axis); to obtain $D_{\mathrm{s}}$ it is of course necessary to consider enough storms to remove the influence of the irregular features peculiar to individual storms.

This was clear to me in 1918, and at that time I particularly wished to know whether $D_{s}$ was opposite in sign, like $D_{\text {st }}$, during the initial phase of the storm, as compared with the main phase. Consequently 1 constructed new Tahles B, on which were entered, according to their local time, magnetic values for shorter intervals of storm-time than one day. On the original Tahles $B_{1}$ and $B_{2}$, each row contained 24 entries, and each average value at the foot of the columns was hased on 40 values (or slightly fewer in some cases, owing to lack of an adequate record of some storms). If an interval of $M$ hours of storm time is taken as the basis of a Table $\mathrm{B}_{\mathrm{m}}$ where $M$ is less than 24, the number of entries in cach row will be $M$ (they will come in different columns for different storms), and the hourly means at the foot of the Table will he hased on only $40 M / 24$ or $5 M / 3$ values. The smaller is this number, the more prominent will be the irregularities of the $D_{s}$ sequence due to the accidental magnetic variations occurring in each storm. In order to he able to reduce $M$ to 4 , I decided to combine the $B_{\mathrm{m}}$ talles (for each element) for the 8 ohservatories above named; tlums if $M=4$, each hourly value in the resulting $D_{\mathrm{s}}$ sequence, based on 4 hours of storm time, and 8 ohservatorics, is an average of $8 \times 5 M / 3$ entries, that is, 53 . For cach of the first four hours of the storm, however, separate $\mathbf{B}$ tables ( $M=1$ ) were made. To reduce the irregularities consequent on the small amount of data involved in the resulting sequences of averages, smoothing was used ly overlapping means of five adjacent numbers, in the case of $M=4$ (but not for $M=1$ ).

This procedure was applied to the $H$ and $E$ data; for the $Z$ data $M$ was taken as 12 , that is, for half days (of storm time).

The $D_{\mathrm{s}}$ sequences thus obtained were completed before the publication of my 1918 paper; owing to war conditions, that paper,
which made no mention of those results, was already too long to be acceptable to the Royal Society, and the original draft was reduced by removing a part ( ${ }^{2-d}$ ), later published elsewhere (1919). At the end of the war in 1918, changes of residence, work, and (for a time) interests, delayed the preparation of an account of the extension of the $D_{\text {s }}$ results; gradually their existence became forgotten, and my 1927 paper did not mention them.

## 6. CRITICISM OF $S_{\text {D }}$ AS NOT TRULY DIURNAL

In 1939 A. G. McNish and H. F. Johnston questioned the diurnal character of $S_{\mathrm{D}}$, in the course of a study ( ${ }^{4}$ ) of the severe magnetic storm of April 1938, which in its most active phase was much shorter than the 4 ) moderate storms I discussed. Their doubts were expred tentatively, as follows.
"Thus one is led to doubt if the anti-symmetrical ( $S_{\mathrm{D}}$ ) field of great magnetic disturbances progresses according to local time. It may be that the 2 -hour period assigned to $S_{1}$ for moderate storms is purely adventitious. However, judgment on this matter must await the examination of a number of great storms" (p. 349).

Later in their paper they wrote: "Chapman has remarked that $D_{\text {st }}$ progresses more rapidly during the greater magnetic disturbances than during the weaker or moderate ones, but presents strong evidence to show that $S_{\mathrm{D}}$ appears to preserve its 24 -hour period. The implication that perhaps $S_{D}$ in also accelerated during this very great storm must be regarded cautiously. The important change in our concepts of magnetic storms, if the conclusion were generalized, emphasizes the need for complete recording of great magnetic storms so that they may be suitably studied $\%$.

Actually, as stated above, I had never myself regarded the matter in this light, though my terminology "residual diurnal variations» (1918) and «disturbance daily variation» (1927) might naturally mislead in this sense. The name is appropriate for the change in the solar daily variation during weak magnetic disturbance (as determined and examined in my 1927 paper), where no storm-time can be assigned because of the lack of a clear epoch of disturbance commencement; but during a storm in which $t_{\mathrm{st}}$ can be measured, the variation that I called $S_{D}$, and now, in that case, prefer to denote by $D_{s}$, represents a geographical distribution of the departure of the storm field from its average value ( $D_{\mathrm{st}}$ ) round each parallel of latitude. Both parts,
$D_{\text {st }}$ and $D_{\mathrm{S}}$, vary with the storm-time $t_{\mathrm{st}}$. This conception was clearly envisaged also by E. H. Vestine and his colleagues ( ${ }^{5}$ ) in their discussion of magnetic disturbance in Chapters 8 and 10 of their monumental "Description and Analysis» (1947).

Owing to the preoccupations of the second world war it was some years before I re-examined the questions raised ( ${ }^{4}$ ) by McNish and Johnston; about 1950 I decided to use my original 1918 data to determine $S_{D}$ or $\left(D_{s}\right)$ at closer intervals; it was a pleasant surprise to find the long-forgotten results already available (and still accessible after over 30 years). The only remaining step was to make a harmonic analysis of the $D_{\mathrm{s}}$ sequences, for the diurnal and semidiurnal components. This was begun by Drs. P. K. Bhattacharya and Wan Cheng Chiu while working with me at the California Institute of Technology, Pasadena, in 1950/1, under a U. S. Signal Corps contract; it was completed in 1952 by D. C. Wilder of the Geophysical Institute of the University of Alaska. The amplitudes were corrected to allow for their reduction by the smoothing process used in the case $M=4$ (§ 5).

The $D_{\mathrm{s}}$ variations were expressed in terms of local time $\lambda_{\mathrm{s}}$, that is, of longitude relative to the sun, measured eastwards from the midnight meridian (opposite to the noon meridian, in the half plane which passes through the sun). In the harmonic analysis they were expressed as

$$
a_{1} \cos \lambda_{\mathrm{S}}+b_{\mathrm{t}} \sin \lambda_{\mathrm{S}}+a_{2} \cos 2 \lambda_{\mathrm{S}}+b_{2} \cos 2 \lambda_{\mathrm{S}}
$$

or

$$
c_{1} \sin \left(\lambda_{\mathrm{s}}+\sigma_{1}\right)+c_{2} \sin \left(2 \lambda_{\mathrm{s}}+\sigma_{2}\right) ;
$$

$a, b, c$ are calculated in force units (gammas) for declination ( $E$, east force) as well as for $H$ and $Z$.

For a storm beginning at Greenwich mean time $t_{0}$, reckoned in angle (at the rate $360^{\circ}$ per solar day) from Greenwich midnight, the local time $\lambda_{\mathrm{s}}$ at a station in longitude $\pi^{\circ}$ east of Greenwich, at storm time $t_{\text {st }}$ (reckoned in angle like $t_{0}$ ), is given by

$$
\left.\hat{i}_{\mathrm{s}}=t_{0}+t_{\mathrm{st}}+i\right)
$$

from which any integral multiple of $360^{\circ}$ may he subtracted. Thus, for a given station, $\lambda_{s}$ is a function of storm time, as well as of the position of the station (and the commencement time of the individual storm).

The coefficients $a, b$, and hence also $c, r$, are all functions of $t_{s t}$.
7. HARMONIC TERMS IN $D_{\text {s }}$ FOR SUCCESSIVE HALF DAYS

In this part of the work all three elements were considered: the results for each day are as follows.

Table 3
Harmonic coefficients of $\mathrm{D}_{\mathrm{s}}$ for the first 4 half days of 40 moderate magnetic storms (mean of 8 observatories); diurnal and semidiurnal components. (Uinit 0.1 gamma).

|  | day | $\mathbf{a}_{1} \quad \mathbf{b}_{1}$ | $c_{1}$ | $\sigma_{3}$ | a | $\mathbf{b}_{2}$ | $\mathrm{c}_{2}$ | 01 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $D_{\text {s }}(\boldsymbol{H})$ | 1 | -12 101 | 101 | $-7^{\circ}$ | -9 | 1 | 9 | -820 |
|  | 2 | 1185 | 85 | 7 | -7 | $-2$ | 7 | -106 |
|  | 3 | 1951 | 5.4 | 20 | -15 | -1 | 15 | -94 |
|  | 4 | $17 \quad 29$ | 34 | 30 | - 5 | -2 | 5 | -113 |
| $D \mathrm{~s}(E)$ | 1 | $75 \quad 8$ | 75 | 87 | 23 | -10 | 2.1 | 104 |
|  | 2 | $63-33$ | 71 | 117 | 11 | 5 | 12 | 65 |
|  | 3 | $23-26$ | 35 | 138 | 19 | 9 | 9 | 7 |
|  | 4 | $13-16$ | 21 | 143 | 4 | 4 | 6 | 45 |
| Ds(V) | 1 | $22-33$ | 40 | 146 | -2 | $-3$ | 4 | 214 |
|  | 2 | - $4-33$ | 33 | 187 | $-3$ | 5 | 6 | 211 |
|  | 3 | $-5 \quad-17$ | 18 | 196 | 5 | 1 | 5 | 79 |
|  | 4 | $-7-11$ | 13 | 212 | 0 | 2 | 2 | 0 |

As was to be expected from the form of the $D_{\mathrm{s}}$ curves in panels $b, c$, of Figures $3-5$ of my 1918 paper, the amplitudes of the second harmonic in Table 3 are small compared with those of the first harmonic; for example, the sums of $c_{1}$ and $c_{2}$. respectively, in Table 3 are (in the units there used) 274,36 for $H, 202,51$ for $E$, and 104 , 17 for $V$. Without a further investigation, based on more extensive data, one can hardly be certain whether the systematic changes shown by $c_{2}$ and $\sigma_{2}$ are real; hence I confine the present discussion of the results to $c_{1}$ and $\sigma_{1}$.

The diurnal harmonic components of $D_{\mathrm{s}}(H)$ riven in Table 3 are illustrated in Figure 3, which is a harmonic dial (cf. pp. 563-6 of Geomagnetism). The four points marked $1,2,3,4$ along the full line, which relates to $D_{\mathrm{s}}(H)$, refer to the successive half days $1,2,3$, 4. For each half day, the point represents the end of a vector drawn from $O$, with length representing $c_{1}$ (on the scale indicated), and with
the direction making the angle $\sigma_{1}$ with the horizontal axis $O b_{1}$. The vertical coordinate of the point is $a_{1}$, the horizontal one is $b_{1}$.

Clearly $c_{1}$ is greatest for the first half day, and steadily diminishes from each half day to the next, while the phase 1 steadily increases; this is clearly illustrated hy the change in the vector from the origin to the points $1,2,3,4$ of the $D_{s}(H)$ line on Figure 3.

The clements $E$ and $V$ show a similar change, but the phase

Fig. 3 - Harmonic dial for the diurnal component of $D_{\mathrm{s}}$ in $H, E$ and $V$, in successive half days of the 40 storms.
for $E$ is about $90^{\circ}$, and for $V$ is about $180^{\circ}$, greater than for $H$, on corresponding half days. The similarity is illustrated in Figure 3 by plotting $c_{1}, \sigma_{1}-90^{\prime \prime}$ for $D_{\mathrm{s}}(E)$, and $c_{1}, \sigma_{1}-180^{\circ}$ for $D_{\mathrm{S}}\left(V^{\prime}\right)$; the lines joining the points for the four half days, in order, are drawn broken for $E$, and dotted for $V$; and these lines are marked $D_{s}^{\prime}(E), D_{s}^{\prime}(V)$, the accents referring to the changes of phase made for these elements; the true harmonic dial diagram for $D_{\mathrm{S}}(E)$ may he got by giving the $D_{\mathrm{s}}^{\prime}(E)$ line an anticlockwise rotation through $90^{\circ}$ about $O$; for $D(V)$, a rotation through $180^{\circ}$ is needed.

The diagram shows that, for the mean of the 8 observatories, $D_{\text {st }}$ on these 4 half days is greatest for $H$ and least for $V$. On account of the small values of $c$; for $V$, this element was not considered in greater detail.

## 8．THE DIURNAL COMPONENT OF $D_{s}$ AT 4－HOURLY INTERVALS

For the elements $H$ and $E$ ，the values of $a_{1}, b_{1}$ ，were determined for each successive group of 4 hourly values from the commencement of the storm（ $\$ 5$ ）．The results are given in Table 4.

Table 4
Harmonic data for the 24－hour component of $\mathrm{D}_{\mathrm{s}}$ in E and H ；mean for 8 observatories．（Unit． 0.1 gamma）．

| Storm time |  | $D_{\mathrm{s}} \quad(H)$ |  | $D_{s}(E)$ |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Hours | Mean | $a_{1}$ | $b_{1}$ | $a_{1}$ | $b_{1}$ |
| $1 / 2$ to $31 / 2$ | 2 | －14 | 66 | 45 | 16 |
| $41 / 2$ to $71 / 9$ | 6 | －34 | 125 | 88 | 9 |
| $81 / 2$ to $111 / 2$ | 10 | 13 | 112 | 91 | $-1$ |
| $121 / 2$ to $151 / 2$ | 14 | 31 | 132 | 98 | －35 |
| $161 / 2$ to $191 / 2$ | 18 | 2 | 80 | 44 | $-33$ |
| 201／2 to $231 / 2$ | 22 | 1 | 44 | 48 | －30 |
| $241 / 2$ to $271 / 2$ | 26 | 4 | 54 | 30 | －29 |
| 281／2 to 311／2 | 30 | 23 | 49 | 21 | －24 |
| $321 / 2$ to $351 / 2$ | 34 | 31 | 51 | 19 | －24 |
| $361 / 2$ to $391 / 2$ | 38 | 13 | 42 | 28 | $-7$ |
| $401 / 2$ to $431 / 2$ | 42 | 19 | 13 | －8 | $-12$ |
| $441 / 2$ to $471 / 2$ | 46 | 18 | 31 | 18 | $-30$ |

These results for $D_{\mathrm{S}}(H)$ are plotted in Figure 4，another harmo－ nic dial，like Figure 3．The results for $D_{\mathrm{S}}(E)$ are not plotted as they stand，but only after modification in two respects：
l）the phase is decreased by $90^{\circ}$ ，as in Fig． 3 （this amounts to plotting each dial with $-b_{1}, a_{1}$ as the $a, b$ coordinates，and

2）magnification in the ratio こ $c_{1}(H) / こ c_{1}(E)$ ，where こ signifies the sum of the four values of $c_{1}$（for $H$ or for $E$ ）in Table 3.

This ratio is $274 / 202$ or 1.36 ．This magnification is made with the aim of rendering the modified $E$ dial points in Fig． 4 comparable with the $H$ dial points，in order to see whether（apart from a constant difference of phase and scale）$D_{\mathrm{s}}(E)$ and $D_{\mathrm{s}}(H)$ as repre－ sented by their main（diurnal）barmonic component，vary in unison， with respect to storm time．

Fig. 4-Harmonic dial for the diurnal component of $D s(H)$ and $D$ 's ( $E$ ), at successive four-hour intervals of storm-time, centred at the epochs $2^{\text {h }}, 6^{\text {h }}, \ldots$

For each 4-hourly epoch of storm time, $2,6, \ldots$, the $H$ and $E^{r}$ (modified $E$ ) dial points are marked $H$ and $E^{\prime}$ and joined by a broken line; the epoch is marked at the mid point of this line.

These $H E^{\prime}$ lines seem to be distributed in a fairly random way,

Fig. 5 - Harmonic dial for the diurnal component of $D_{s}(H)$ and $D_{s}^{\prime}(E)$, for the storm-time hours $01 / 2$ to $31 / 2$.
supporting (though hardly establishing) the expectation that $D_{\text {s }}(H)$ and $D_{\mathrm{s}}(E)$ vary similarly with respect to storm time (the $E^{\prime}$ points mostly lie somewhat ahove the $H$ points, as also in Fig. 3, suggesting that the phase difference $90^{\circ}$ between $E$ and $H$ is only approximate).

The mid points of the $H E^{\prime}$ lines are taken to represent the dial vector for $D_{\mathrm{s}}$ for $H$ and $E^{\prime}$; they are joined in succession by a full line. This $D_{\mathrm{s}}$ line is of course affected by random errors, and the curved broken line in Fig. 4, extending from 2 to 18 hours, is a tentative smoothed representation of the course of $D_{\text {s }}$ during this interval.

It suggests that $c_{1}$ for $D_{\mathrm{s}}(H)$ and $D_{\mathrm{s}}(E)$ increases from zero (at zero storm time) very rapidly to $2^{h}$, and then more slowly up to about $10^{11}$, when it attains its maximum; and then in the next 8 hours, to $18^{h}$, it decreases to about the same value as at $2^{\text {h }}$, after which its rate of decrease quickly declines. During the period from ahout $6^{\text {b }}$ to $14^{\text {h }}$ the phase angle $\sigma_{1}$ increases by about $30^{\circ}$. The maximum value of $c_{1}$, at ahout $10^{1}$, is about 13 gamma; this applies to $D_{s}(H)$, and is reduced in the ratio $202 / 274$ to ahout 10 gamma for $D_{\mathrm{s}}(E)$.

## 9. VARIATIONS OF $D_{\text {s }}$ DLiRING THE FIRST 4 HOURS

The values of $a_{i}, b_{1}$ for $D_{s}(H)$ and $D_{s}(E)$ in the first four individual hours of the average storm are given in Tahle 5.

Tablef 5
Harmonic coefficients for the 24-hour component of $\mathrm{D}_{\mathrm{s}}$ in E and H , for the first four separate hours of storm time; mean for 8 observatories. (Unit 0.1 gamma)

| Storm time | $D_{\mathrm{s}}$ |  | $(H)$ | $D_{\mathrm{s}}$ |  | $(E)$ |
| :---: | ---: | ---: | ---: | ---: | :---: | :---: |
|  | $a_{1}$ | $b_{1}$ |  | $a_{1}$ |  |  |
|  |  | $b_{1}$ |  |  |  |  |
|  |  |  |  |  |  |  |
| $01 / 2$ | 25 | -12 |  | 11 |  |  |
| $11 / 2$ | -16 | 75 | 37 | 0 |  |  |
| $21 / 2$ | -33 | 93 | 57 | 24 |  |  |
| $31 / 2$ | -32 | 109 | 76 | 15 |  |  |

These results are plotted in Fig. 5 in the same way as were those of Table 4 in Fig. 4, with the same change of phase and scale for $D_{\mathrm{s}}(E)$. Each dial point in Fig. 5 is hased on only one quarter the amount of data underlying each point in Figure 4, and greater
random error may he expected; it is surprising that the lengths of the $H E^{\prime}$ lines, which perhaps partly indicate the random error, are not notahly greater in Fig. 5 than in Fig. 4. The point for $01 / 2^{11}$, however, which has the least value of $c_{1}$, may he unreliable hy more than its whole small magnitude, and its phase angle is very uncertain. The positions of the points for $1 / 2,21 / 2$ and $31 / 2$ hours are much as might he expected, and suggest that $c_{1}$ increases most rapidly during the first hour. There is no valid evidence as to whether or not $D_{\mathrm{s}}(H)$ is reversed during this first hour, but it would certainly seem to have the same sign from $l^{h}$ onwards. As $D_{s}$ in any case semms to he small during the first hour, much more material and a more careful treatment will he needed to determine how it then varies; and the same applies to the end of the second day, when again $c_{1}$ has become small (Fig. 4). The uncertainty of the magnitude and phase of $D_{s}$ at these early and late times is due not only to the relatively greater ratio of the probable error to $c_{1}$, when $c_{1}$ is small; the uncertainty depends also on the question whether the position of the origin of the dials in Figs. 4,5 is correct.

As explained in Section $3 b$ of this paper, in my determination of $D_{\text {s }}$ the mean solar daily variation $S$ for all the storm-months was subtracted from the mean sequence derived on each Table B; this $S$ certainly involves some $S_{\mathrm{b}}$ in addition to $S_{\mathrm{G}}$, and the $S_{\mathrm{p}}$ will be somewhat greater for these storm months than for months less disturhed. A careful determination of this subtracted $S_{D}$ would be required in order to locate the correct position of the origin in Figs. 4, 5. This has not been undertaken here hecause I hope ere long to organize a new and more thorough investigation of magnetic storm morphology, based on considerahly more extensive data, as regards both the number of storms and the number of ohservatories. Meanwhile the nature of $D_{\mathrm{s}}$ in the first hour of the storms remains in some doubt.

## 10. COMPARISON OF THE RATES OF GROWTH AND DECAY OF $D_{s t}$ AND $D_{s}$

The range of the $D_{\mathrm{s}}$ variation at any epoch of storm time is $2 c_{1}$, and it is interesting to compare this with the value of $D_{\text {st }}$ at the same epoch. This is done, for the mean of the 8 observatories, in Fig. 2; the values of $2 c_{1}$ for the storm hours $6,10,14,18$ are taken from the (smoothed) Fig. 4, and those for 30 and 42 from Table 3 for $D_{\mathrm{s}}(H)$. The values for the first four hours, and their mean, are
from Tahles 5, t; the point nearest the beginning of the storm is rather uncertain.

Despite the accidental error inevitable in the diagram, Fig. 2 shows that $D_{\mathrm{s}}$ ( $I$ ) follows a course very different from that of $D_{\mathrm{st}}(H)$; it attains its maximum earlier, and then decreases much more rapidly; and if it suffers any reversal near the storm commencement, this is over very quickly, well before $D_{\text {st }}(H)$ reverses.

## 11. CONCLUSION AND ACKNOWLEDGMENTS

The methods of the present paper should be further applied, to determine the progression of $D_{s}$ in higher latitudes, at different seasons, and for groups of storms graded in intensity: and also to ionospheric storms.

I hope soon to publish (in the forthcoming Supplementary Volume, dedicated to Professor F. J. M. Stratton, F.R.S., of the Journal of Atmospheric and Terrestrial Physics) a general review of the morphology of magnetic storms: some of the results of the present paper will there be considered in connection with the development of the great storm of April 1938 ( ${ }^{4}$ ).

In conclusion, it is a pleasure to acknowledge the assistance received in some of the calculations of this paper from Drs. P. K. Bhattachariya and Wan Cheng Chiu, and from D. C. Wilder of the Geophysical Institute of the University of Alaska, who also prepared the diagrams.

The Queen's College, Oxford and the Geophysical Institute, University of Alaska - September 1952.

## SUMMARY

The «D» field of magnetic disturbance has in the past been analysed into a part $\mathrm{D}_{\text {st }}$ depending on time reckoned from the storm commencement -- storm-time - and a part whose distribution has a simple form relative to the meridian containing the sun. This part reveals itself at times of weak or moderate magnetic activity as an addition to the field of the solar daily magnetic variation (S), present in its pure forme $\mathrm{S}_{11}$ on quiet days; the addition is called the disturbance daily variation, denoted by $\mathrm{S}_{\mathrm{p}}$. But during storms with definite commencement, the average course of this part of the D field, which is
non-uniform round the earth, and is oriented in a definite way relative to the noon meridian, can be followed not only from one day to the next, as has been done in the past, but over shorter periods, even from hour to hour; as then studied, it is not a daily variation at all, but a distributed field changing in form and intensity with storm time. This part of the field is here called the $\mathrm{D}_{\mathrm{s}}$ field, or disturbance (solar) local-time inequality. It varies with storm time in a manner materially different from $\mathrm{D}_{\text {st, }}$, developing more rapidly than the main phase of $\mathrm{D}_{\mathrm{st}}$ and decaying much faster.
